1. INTRODUCTION

Archeology – the study of human culture through excavation and examination of material remains – helps us understand the lives and practices of the people who came before us. Archeology can illuminate the lives of those who did not leave a written record, including prehistoric indigenous groups such as Native Americans. Where archival documents or oral traditions exist, archeology can still fill in missing pieces of the historical record, helping to ensure that people ordinarily forgotten or intentionally excluded (for example, enslaved African Americans or poor industrial workers) are featured in our explanations of the past. Likewise, certain aspects of daily life (for example, how and what people ate, what constituted a “typical” household, or the lives and activities of children) may be mischaracterized or absent from written records, leaving archeology to provide a more complete, less biased representation of the past.

The research, preservation, and interpretation of archeological sites can also contribute to the local, state, and national economy. Museums, historic sites, and educational programs use archeological data to better interpret Maryland’s past. When exhibits and tours include direct access to archeological sites and artifacts, visitors can engage with tangible pieces of our shared history, facilitating a more direct, and often more memorable, connection. In addition to educating Maryland residents, these efforts help bring tourists to a community, contributing to the local economy.

Finally, by linking the past to the present, archeology can also inform the future. Archeology can illuminate social, environmental, and economic trends over long periods of time, helping us understand contemporary patterns as well as future possibilities. In an era of climate change, this aspect of archeology may become increasingly relevant, as living people seek to learn more about how humans have adapted to changing conditions.

Archeology under Threat

The Chesapeake Bay, rivers and other waterways have long provided humans with transportation routes, food and other resources. Many areas associated with Maryland’s historic and prehistoric human activity are therefore located adjacent

Maryland Archeology Month 2017

AT THE WATER’S EDGE: OUR PAST ON THE BRINK

In 2017 MHT addressed the effects of flood hazards on archeological sites by making it the theme of Archeology Month.
to water and are prone to flooding. As sea levels rise and storms become increasingly intense and frequent, the effects on archeological resources will be devastating. Riverine sites will be eroded away by precipitation and flash floods. Coastlines will be remodeled by storm surge and scoured by increasingly higher tides, eroding coastal sites until nothing remains. Resources that were once dry or only intermittently wet will be subject to longer or permanent inundation. These factors can lead to the deterioration of floral and faunal materials, delicate artifacts, and archeological features (refer to “Flood Impacts to Archeological Sites” in Section 3). Losing these materials will diminish our ability to understand and interpret past lifeways and cultures.

Although this document is geared toward non-archeologists, the actual work described must be undertaken by qualified archeologists (refer to Section 2). Unfortunately, many local governments do not have qualified archeologists on staff. Some communities have addressed this gap by hiring archeologists as consultants on an as-needed basis. While there is no universal solution, local governments can apply for grants, including through MHT, to undertake archeology projects with the help of qualified professionals (refer to Appendix 2: Funding Sources).

This guidance document will help local government planners understand how to identify archeological resources and sites in flood-prone areas and how flooding can affect those sites. The document outlines considerations for protecting or examining such sites, as well as options for resources that may not be able to be saved. The Maryland Historical Trust (MHT) encourages planners to consult with MHT staff archeologists prior to launching flood protection or mitigation plans that may affect archeological sites. MHT is also available for technical assistance throughout the duration of the project.

Who Should Use this Planning Document?

This document’s intended audience is planners in local government with limited archeological experience. As such, a large portion of this document is devoted to basic information about the practice of archeology, including an explanation of what archeology is, where archeological sites occur, and who is qualified to conduct archeological work in Maryland (refer to Section 2).
This background provides the context for subsequent sections that define flood hazards (refer to “Mapping the Flood Risk to Known Archeological Sites” in Section 3), explain how to assess the threats they pose to archeological sites (refer to “Flood Impacts to Archeological Sites” in Section 3), and outline how to reduce the effects of those threats (refer to Section 7). The Additional Resources at the end of this guidance will direct the reader to more information on the topics discussed.

Planning for Maryland’s Flood-Prone Archeological Resources is an introduction to the issues and options surrounding archeological sites and the threat of flooding. Readers may also wish to consult MHT’s Flood Mitigation Guide: Maryland’s Historic Buildings, developed to provide local governments with a planning process that balances historic preservation and flood protection. The Flood Mitigation Guide also provides a primer on floodplain management regulations, the National Flood Insurance Program, and the emergency management cycle, which are not covered in this document. The planning process in the Flood Mitigation Guide may also be applied to archeological resources and can be used in conjunction with this guidance to develop projects to include in local hazard mitigation plans which also address vulnerable archeological resources. In time, these planning documents may be updated, refined and combined into a single guidance document or toolkit for local governments with historic and cultural resources threatened by flooding.
2. WHAT IS ARCHEOLOGY?

Archeology is the study of ancient and recent cultures through the examination of material remains. Material remains are any physical objects from the past – including objects as large as a building foundation or as small as a piece of pottery – which can help archeologists better understand human activity. Archeology may supplement the historical record or be used to research cultures when historic documentation is limited, unreliable, or altogether non-existent. Archeology can include any part of the process of identification, excavation, preservation, or analysis of material remains, and can encompass sites on land and underwater. Archeology involves many activities including library research, remote sensing with tools that “see beneath the soil,” survey work to identify sites, the meticulous excavation and recording of artifact locations, cataloging and conservation of artifacts, lab analysis, and reporting of results.

Of course, archeology involves more than just “digging for artifacts.” An archeological site contains a concentration of material remains from the past, and the location of artifacts (refer to highlight below) and features (refer to highlight on p. 11) in relation to one another helps the archeologist make determinations about the sequence and nature of human activity at the site. This context, and proper recordation, is in many ways more important than the artifacts themselves. Once taken out of context, an artifact can yield little to no scientific data.

The vertical context of the site usually refers to the location of an archaeological find in the strata.
(soil layers) of the earth. Accurate recordation of vertical context helps the archeologist evaluate changes though time. The deeper an artifact or feature sits, the further back in time it may originate. The horizontal context of the site refers to how objects within the same strata, but separated horizontally, relate to each other. Horizontal contexts are important to making determinations about contemporaneous activities at the site, as artifacts and features in the same horizontal context are often associated with the same period of time.

Given the importance of archeological context, archeologists have developed methods for each stage of archeological investigation to ensure both the appropriate recovery of artifacts and the accurate documentation of locational data. Following background research, archeologists usually begin investigations with field survey, oriented towards the discovery of new sites or locating the boundaries of existing sites. Archeologists use techniques such as controlled surface collection or the excavation of shovel test pits at regular intervals to locate sites. Controlled surface collection involves using survey instruments (such as compass and tape, a surveyor’s transit, or GPS) to lay out a grid of “collection squares” or linear transects, and then collecting and recording the position of all of the artifacts encoun-

---

**FEATURES**

Features are fixed elements within an archeological site that relate to the people who utilized that location in the past. A buried house foundation is an easy-to-understand example of a feature. Unlike an artifact, a foundation cannot be removed from the site without being dismantled. Thus, archeological attention to features generally focuses on detailed documentation rather than removal and recovery. Features are often identified by a change in color or texture in the soil from the surrounding strata, or a clustering of artifacts that cannot be removed from the site in its original configuration. Features can include, but are not limited to, post holes, hearths and firepits, trash pits (middens), walls, and pathways. Features will often contain artifacts in their original context (reference Section 2) and provide important information for interpreting a site. Artifacts found within a feature can help archeologists recognize the feature’s original function and, hence, the function(s) of the site.

Brick feature exposed at the Smith St. Leonard site.
112. WHAT IS ARCHEOLOGY?

When an archeological site is the subject of more rigorous in-depth study, archeologists will often dig in formal test units. These test units are usually a standardized size (such as 5x5 ft or 2x2 meters), and all artifacts and features encountered are recorded within a given square or transect. Shovel testing involves digging small test holes (about the width of a shovel blade and 50-100 cm deep) at regular intervals and then recording the location of each shovel test pit as well as any artifact finds. In this way, archeologists can discover new sites and better define the boundaries of known sites.

When an archeological site is the subject of more rigorous in-depth study, archeologists will often dig in formal test units. These test units are usually a standardized size (such as 5x5 ft or 2x2 meters), and all artifacts and features encountered are recorded within a given square or transect. Shovel testing involves digging small test holes (about the width of a shovel blade and 50-100 cm deep) at regular intervals and then recording the location of each shovel test pit as well as any artifact finds. In this way, archeologists can discover new sites and better define the boundaries of known sites.

in each test unit are recorded on paperwork specific to that unit and stratigraphic level. Archeologists record the locations of test units on a detailed site map and often record the locations of items within a test unit down to the nearest centimeter or fraction of an inch. Such in-depth study and recordation is usually associated with either academic research or evaluation of a site to determine its significance and/or the time periods or cultures represented by the artifacts recovered.

2. WHAT IS ARCHEOLOGY?
Once archeologists complete the analysis of the artifacts, the artifacts must be conserved, along with their associated records. Artifacts should be placed in a repository, such as the Maryland Archaeological Conservation Lab (MAC Lab) at Jefferson Patterson Park and Museum, with curators who have specialized knowledge of how to preserve artifacts and archeological records. As the final step in an investigation, archeologists prepare and publish a site report to disseminate site data to the archeological community and assist in future research and investigations.

When artifacts are removed from their original context without the accompanying paperwork and locational information described above, the individuals doing the “removing” are not practicing archeology. Tourists and relic hunters can cause serious damage, whether intentionally or not. Common but harmful practices include collecting arrowheads or using metal detectors to find artifacts to keep or sell. Collection without meticulous recordation and reporting reduces the information potential of a site and detracts from our knowledge about the past. For this reason, federal law prohibits the collection of artifacts and disturbance of sites on federal land. Likewise, Maryland law requires special permitting to remove artifacts from state-owned lands and waters (such as state parks, wildlife management areas, tidal rivers, and navigable non-tidal rivers). Increasingly, local jurisdictions are also creating laws to protect archeological sites and artifacts, but protection on private land depends largely on private landowners. In Section 7, this document outlines some of the ways a local government might engage with the public and landowners to include them in the planning process and avoid harm to archeological sites.
132. WHAT IS ARCHEOLOGY?

Archeologists engage in their practice for research, planning, and regulatory purposes. Non-profit organizations (e.g., the Archeological Society of Maryland and the Lost Towns Project) and universities and colleges undertake archeology for pure research, as do some state and local government agencies (including MHT) that have professional archeologists on staff. Some counties and municipalities, through professional staff or contractors, review development proposals for archeological impacts and otherwise plan for the protection and interpretation of local archeological resources. Archeological research and planning activities are generally funded by grants, including Historic Preservation Non-Capital grants and Certified Local Government grants available via MHT (reference Appendix 2: Funding Sources).

Local project review for archeology occurs based on regulations and policies set forth by the local government. However, many local governments lack the staff capacity or expertise to conduct these reviews. MHT recommends that local governments hire a qualified archeologist to serve in the local planning office or another branch of local government, but this may require enacting local legislation or getting the “buy in” of local elected officials to create such a position. Alternative strategies could include contracting with a cultural resource management firm or archeological consultant to serve as a local government consultant.

Many archeological surveys are carried out as a result of the federal and state historic preservation review process established under Section 106 of the National Historic Preservation Act (36 CFR 800), as amended, and the Maryland Historical Trust Act of 1985, as amended (§5A-325 and 326). Both laws require federal and state agencies to consult with MHT regarding any project that involves federal or state funds, permits, or licenses to assess their potential impacts to historic properties, including archeological sites. (For more information about related legislation, see Appendix 5: Legislative and Regulatory Background.) Typically, archeology conducted for federal and state regulatory purposes is undertaken by contractors, on behalf of the project sponsor or solicited directly by the involved federal or state agency.

Museums, living history sites, colleges and universities, and local historical societies can and should make use of archeological data. The public generally has a strong interest in history (especially local history) and prehistory. Guided by qualified staff, planners and local government officials can play a role in bringing archeology to the local level. Unfortunately, disseminating archeological data is often difficult. Once artifacts go to a curatorial facility (see above) or site reports are accepted as legally sufficient to meet state and...
federal laws, they have a tendency to be forgotten.

To help make archeological information more accessible, MHT has begun making some classes of data available to the public. The Maryland Archeological Synthesis Project (described further in Section 3) makes capsule summaries of many site reports available to the public for free over the internet. Collections donated to the state or curated at the MAC Lab are available for further research, traveling exhibits, and long-term loans. While not a substitute for qualified archeological staff, tools such as the Diagnostic Artifacts webpage and Small Finds database can provide planners with valuable resources they can use in trying to understand local archeology and engage the public in the preservation of archeological resources.

Who is Qualified to Conduct Archeological Work?

Archeological investigations should only be conducted by or under the direct supervision of individuals who meet or exceed the Secretary of the Interior’s Professional Qualifications Standards (36 CFR 61). The minimum professional qualifications in archeology are a graduate degree in archeology, anthropology, or a closely related field plus:

1. At least one year of full-time professional experience or equivalent specialized training in archeological research, administration or management;
2. At least four months of supervised field and analytic experience in general North American archeology, and
3. Demonstrated ability to carry research to completion.

In addition to these minimum qualifications, a professional in prehistoric archeology shall have at least one year of full-time professional experience at a supervisory level in the study of archeological resources of the prehistoric period. A professional in historic archeology shall have at least one year of full-time professional experience at a supervisory level in the study of archeological resources of the historic period.

Archeology undertaken to comply with federal and state regulations, or to support projects funded by the federal government or the State of Maryland, must be conducted by professionals who meet the Secretary’s Professional Qualifications Standards. The work must also comply with MHT’s Standards and Guidelines for Archeological Investigations in Maryland, which provide a methodology for conducting investigations and a format for the report that documents the investigation. MHT recommends that all archeological work conducted in Maryland adhere to these Standards and Guidelines whether or not it is required as part of the investigation.
Maryland’s diverse archeological heritage spans over 12,000 years of human occupation and demonstrates to us how the state’s rich natural environment - from the tidal wetlands of the Eastern Shore to the forests of the Appalachian Mountains – has supported people throughout prehistory and history, to the present day. The archeological sites that remain today are irreplaceable: they are tangible links to the past, providing data that is not otherwise readily available. Found in rural areas and urban settings, sites include, but are not limited to: Native American villages, encampments, shelters, and resource procurement areas; Colonial towns and farmsteads; plantations, associated landscape features and outbuildings, including slave quarters; fortifications and battlefields; industrial complexes, such as mills, tanneries, or iron furnaces; infrastructure, such as historic military roads, dams, or canals; and historic residential and commercial sites, such as cabins, inns, or taverns. Common underwater archeological sites in Maryland include shipwrecks; piers, wharves, boatyards, and landings; and inundated sites, from all time periods, that become submerged as a result of coastal changes. It is important to note that while the locations of many archeological sites have been documented (as discussed in this section), many more are unknown or undocumented (refer to Section 4); both known and unknown sites are vulnerable to flooding.

Archival and Background Research on Known Archeological Sites

To plan for the protection, research, or interpretation of archeological sites, the first step is understanding what sites have been identified and documented. MHT maintains an inventory of known archeological sites in Medusa, Maryland’s Cultural Resource Information System, collected via the Maryland Archeological Site Survey (MASS) form. Due to the threat of looting and vandalism, the location of archeological resources is considered sensitive information. MHT allows full access for agency representatives, archeologists and researchers who meet the Secretary of the Interior’s Professional Qualifications Standards (refer to Section 2). To obtain access to archeological site files, you must request a Medusa account online.

In addition to site location, archival and background research will help illuminate the known significance and integrity of sites for prioritization purposes (refer to Section 3), identify sites that were documented and destroyed (so are no longer a factor for planning), and help planners understand what additional areas may need to be researched (refer to Section 6). When conducting background research to learn more about potential sites at risk, or prior to beginning an archeological investigation, researchers should always consult MHT and the local county government for information on previous investigations and local history/prehistory. Because archeological data is restricted to protect site location information, it is imperative that local planners work with a qualified archeologist to undertake this work, either by having this expertise on staff or by hiring a consultant.

Located at its headquarters in Crownsville, the MHT Library currently includes site-specific archeological survey reports, maps, slides, and documentation for over 14,000 terrestrial and underwater archeological sites. The MASS forms, available online through Medusa, are also filed in the library along with extensive hard copy research for each site, which often includes more detailed information than is accessible online. Many site reports describe the results of past
fieldwork activities and catalog artifact finds. Like the online locational records, access to archeological documentation in the library is by appointment only and is restricted to qualified researchers who have been approved by MHT archeological staff. Before visiting the MHT Library, individuals should apply online for a Medusa account.

The MHT Archeological Synthesis Project consists of a searchable database that links the MASS data to additional information housed in the MHT Library, including excavation synopsis reports and cover sheets. Synopsis reports contain a capsule summary of the overall site report, organized in a way that makes it easier for researchers to quickly pull out the most relevant information they would need to understand the past activities at a site. The cover sheets address the history of archeological activity at a site, including the justifications for fieldwork, research objectives, and the potential for future research at the locale. For members of the general public, detailed geographic information is restricted to protect site locations, but all other data is otherwise present. Qualified users can access more accurate geographic information.

Located in Calvert County, Jefferson Patterson Park and Museum (JPPM) is the State Museum of Archeology and part of MHT. JPPM houses the Maryland Archeological Conservation Laboratory (MAC Lab) as well as a large research library with references on archeology and related topics, as well as references specific to Maryland history and prehistory. The library is open to researchers, students, and the public by appointment only. Information on diagnostic artifacts in Maryland, paleobotanical data, colonial Chesapeake cultures, collections guides and finding aids, and other information is available online through JPPM’s website.

The Maryland Unearthed website provides access to many of the important archaeological collections maintained by the Maryland Archaeological Conservation Laboratory, the state’s central curation facility.
To determine how flooding might impact local archeological sites, the next step is to contact the local emergency management office, which prepares the local hazard mitigation plan, to learn more about what types of flooding affect the area of interest. The hazard mitigation plan will provide information on the occurrence of flood hazards within a County and its municipalities. (Annapolis, Baltimore, and Ocean City have separate municipal plans.) The hazard mitigation plan assesses the vulnerability of local jurisdictions and will serve as a useful starting point, but it is unlikely to address the impact at the scale needed to determine the effect on individual archeological sites. Hazard mitigation plans very rarely include climate change projections. (Refer to the Flood Mitigation Guide, Section 2: Planning and Preparedness for more information on hazard mitigation plans, other planning options, and how to integrate cultural resource planning into these processes.)

With information about local archeological sites plus information about local flood risks, it is possible to overlay these maps with one another using tools like Geographic Information Systems (GIS) to better understand the risk to sites within the area of interest. Common mapping tools for different types of flood risks are outlined below. GIS layers for cultural resources are available as ESRI shapefiles from MHT to qualified archeologists. MHT’s GIS data access policy is available online.

It is important to note that overlaying data layers provides a rough assessment of vulnerability and only encompasses known archeological sites. An in-person assessment would be needed to understand the actual vulnerability of a site. (Refer to “Vulnerability Assessments” in Appendix 3.)
Flood Zones. Information on flood risk is maintained by FEMA on Flood Insurance Risk Maps (FIRMs), which delineate areas of high, moderate, and low risk to flooding from riverine and coastal sources. The high-risk area or Special Flood Hazard Area (SFHA) is commonly called the “100-year floodplain,” meaning that FEMA estimates a one-percent annual chance of flooding in this area. The SFHA is the area in which local jurisdictions apply their floodplain ordinances. The area of moderate risk delineated on FIRMs is known as the 0.2 percent annual chance floodplain or “the 500-year floodplain.” Unlike the SFHA, the flood depths have not been determined in the moderate risk zones. FIRMs also include information about wave height and action.

Areas beyond the 0.2 percent annual chance floodplain are considered low risk for flood hazards. However, low risk does not mean no risk. Recent storms such as Hurricane Matthew in North Carolina (2016) and Hurricane Harvey in Houston (2017) caused flooding and tremendous damage to buildings located outside of the delineated high and moderate risk flood areas. Flood zones are established based on historical data, not future projections, and frequent and more intense storms are predicted as part of a changing climate. For this reason and others, it is important to consider how vulnerabilities may change over time.

Flood zones can be used to delineate basic areas of risk to archeological resources: recorded sites located within the SHFA could be deemed at a high risk to flood impacts; those within the 0.2 percent annual chance floodplain at moderate risk; and those beyond the 0.2 percent annual chance floodplain at low risk. More sophisticated assignments of risk could factor in different wave...
heights (e.g. the higher the wave heights, the more damage), proximity to flood source within the high flood risk areas, and/or climate projections. The more sophisticated the analysis, the more likely it is that it should be done by someone who has specialized knowledge about the functions of floodplains, like the local floodplain administrator or a Certified Floodplain Manager working in conjunction with an archeologist.

FIRMs and supporting data are available for download as GIS layers in the Flood Risk Application maintained by the Maryland Department of the Environment (Refer to “GIS Resources” in Appendix 3). (For more information on how to read a FIRM and understanding floodplain management, refer to the Flood Mitigation Guide, Section 1.A. Flooding and Section 1.B. Floodplain Management.)

Storm Surge. Mapping that depicts the extent of the predicted storm surge associated with hurricanes is generated using the GIS application Sea, Lake, and Overland Surges from Hurricanes (SLOSH). The SLOSH program creates a model incorporating the wind field of hurricane categories 1-5, which drives the storm surge based on estimated values from historical, hypothetical and/or predicted hurricanes, while also accounting for atmospheric pressure, size, forward speed and wind data (National Weather Service, 2018). The model forecasts the predicted reach (horizontal extent) and height or depth (vertical extent) of water surge above ground level. The SLOSH pro-
gram then produces a map of inundation levels based on the five categories of hurricanes. Static SLOSH GIS layers are available to view through a variety of sources: the local government’s Office of Emergency Management (or department responsible for updating the local hazard mitigation plan), MDE’s Maryland Flood Risk Application, and the National Weather Service (refer to “GIS Resources” in Appendix 3). Determining risk could be as simple as overlaying the locations of archeological resources with the storm surge layers. For those who feel confident using the SLOSH application themselves, the locations of archeological resources can be imported into the application and used to create models that show the predicted depths and velocity of surge at specific locations, as was done for Hunting Creek in Calvert County (Tyler et al, 2017) (refer to Case Study #2 in Appendix 1). If SLOSH is used for specific locations, there will be quantifiable impacts to those specific areas.

Shoreline Erosion (Riverine and Coastal). Many factors contribute to the loss of a shoreline, such as whether adjacent shorelines are armored; the presence or absence of breakwaters, such as jetties; the movement of water towards the shore; the soil composition; and the presence or absence of a vegetative covering. Basic information on shoreline erosion is available through Maryland iMap for several counties (refer to “GIS Resources” in Appendix 3).

Rates of shoreline erosion can also be determined using GIS applications (described below), or by analyzing various characteristics (geology, geography, hydrography) at specific locations to quantify the risk of erosion to individual archeological sites. Determining rates of shoreline erosion is a complicated endeavor best done in consultation with a specialist such as a coastal geomorphologist. Two different examples of how to determine the rate of shoreline erosion are presented in Appendix 1: Case Studies.

Sea Level Rise. The Maryland Commission on Climate Change produces periodic reports on sea level rise projections for the state. Current estimates support planning for a rise of 2 feet by 2050 and up to 3.7 feet for 2100. It is therefore useful to consider the timeframe for planning when establishing flood risk to sites in areas vulnerable to sea level rise.

The GIS maps and data available through Maryland iMap and in MDE’s Flood Risk Application show inundation layers of 0 to 2 feet, 2 to 5 feet, and 5 to 10 feet of sea level rise (refer to “GIS Resources” in Appendix 3). The layers are based on high-resolution topographic data obtained from local and federal agencies. An analysis of the vulnerability of archeological resources to sea level rise can be determined as high, medium, or
low risk depending on the placement of known sites within the layers. (To explore an application that combines architectural inventory layers from Medusa with sea level rise inundation layers, visit [http://mdpgis.mdp.state.md.us/historicslr/index.html](http://mdpgis.mdp.state.md.us/historicslr/index.html).) Not surprisingly, nearly 3,000 of Maryland’s known archeological sites are located in areas that are considered to be vulnerable to inundation and flooding in the event of a 2-foot sea level rise.

**Increased Precipitation Due to Climate Change.**

Increased precipitation due to heavier rain, storms that stay in place for a long period of time, and more frequent storms, is anticipated in the Chesapeake Bay region as a result of climate change. Increased precipitation saturates the ground for longer periods of time and can contribute to flash flooding and scouring. Unfortunately, state and local planners do not currently have access to models showing the projected increase.

**Flood Impacts to Archeological Sites**

Flooding impacts the physical properties of archeological sites, including features and artifacts. Artifacts in situ (in the last location they were left by a human) convey information by their horizontal and vertical location within the site, as they relate to other artifacts, features and the site (refer to Section 2). Unfortunately, flooding remodels landforms both horizontally and vertically, and saturation in floodwater can destabilize the ground, causing shifting, heaving, or subsidence. Any disturbance or mixing of strata will disrupt the temporal and cultural sequence of the site, mixing resources from different time periods and cultures. Floodwater can also introduce contaminants, change the composition of soils, and transport debris. If one part of a site becomes damaged or altered by flooding, that information is lost, while also severing the relationship of that part to the site as a whole. In these ways, described in more detail below, flooding can damage the ability of an archeological site to yield information about the past (reference Section 5). The impact of a flood depends on its characteristics, the geographic context of the archeological resources, and the composition of the resources. Flooding has three key characteristics: depth, velocity (how swiftly the water moves), and dura-
tion (how long areas remain inundated before the water recedes). However, the ground cover and composition of the land affects those three characteristics. For example, narrow, restricted river valleys or man-made concrete channels can funnel floodwater and increase the depth and velocity of the flow. Open land can reduce velocity because of the friction provided by vegetation and can spread water across a larger area, reducing flood depths. If the ground is already saturated from recent storms, its ability to drain might be compromised, keeping areas wet longer. Clay soils and rock are less absorbent than silty or sandy soils. Marshes can act as sponges, absorbing floodwaters. Impervious surfaces like concrete do not absorb water; instead, the water flows along the surface until it reaches a point where it can drain away. Therefore, depending on the kind of flood and the geographic context of an archeological site, the damage to the site may vary significantly.

Water can have numerous deleterious effects on archeological resources. Sites that are preserved because they are dry can degenerate in water. Water washes away delicate materials like microscopic pieces of flora and fauna, which could indicate, for example, what type of diet was consumed at a site. Water can break down charcoal which might be useful for radiocarbon dating of a site. Saltwater can change the pH of soil, making it more acidic and prone to dissolve certain types of archeological resources such as bone or other organics. Flood water can also be contaminated with hazards, including sewage, gasoline, motor oil, fertilizer, and dead animals. If floodwater is contaminated with a particularly corrosive material, the archeological resources could breakdown even faster, especially materials that are more water-sensitive like metal.

Floodwater transports and redeposits debris. We commonly think of debris as sediment from scoured riverbanks or coastal areas, rocks, trees, and other natural materials, but archeological resources can be removed by floodwater and redeposited elsewhere. This causes sites to lose integrity because the artifacts are no longer associated with their original location. Floods can also deposit other materials on top of a site, inter-
rupting its stratigraphy. If flood water removes plants and exposes the underlying soils, it may also expose archeological resources, increasing their vulnerability to multiple threats, including looting.

Once exposed, subsequent floods can undercut riverbanks to the point of failure and collapse, destroying all or part of a site. Flash floods can cause tremendous damage due to the volume and velocity of floodwater and can also scour riverbanks. Coastlines are typically at risk to more consistent erosive forces than riverbanks, due to wave action, winds, and storm surge. Primary effects of coastal erosion include damage due to collapse or loss of portions of the coastline, as well as the abrasion and removal of strata which scatters artifacts across the land and water.

Coastal storms like hurricanes and Nor’easters compound the damages caused by flooding by bringing multiple flood hazards to bear. When high tides occur during these storms, the added volume of water creates deeper flooding that pushes further inland. Barrier islands, sand bars, and high projections of land that parallel the shoreline may protect the shoreline by reducing the velocity of storm surge and dissipating the destructive energy of waves. However, hurricanes can cut new channels through inlets and remodel coastlines. When landforms are cut through, that cut forms a funnel through which waves can pass, making the new cut or inlet itself vulnerable to erosion. In time, these changes may eventually cause the loss of the whole landform and any archeological sites in the area. Response and recovery activities can also damage archeological sites. While local governments seek to establish debris management areas (dedicated locations to receive, sort and dispose of flood debris) away from known archeological sites, there is always a chance that they might be located on an unrecorded site. Post-disaster debris clearance is usually conducted using heavy equipment, potentially damaging or destroying known or unknown sites within the clearance area. Repairs to infrastructure and buildings may also reveal and harm archeological resources.

Because the impacts of flooding are so nuanced and dependent on the individual characteristics of the flood, geographic context, and site(s), planners should, ideally, follow the mapping exercise for known archeological sites with additional investigations. These investigations could include researching the potential locations of archeological sites (refer to Section 4), and/or more detailed investigations of the vulnerability of high-priority areas or sites (refer to Section 7).

4. IDENTIFYING POTENTIAL ARCHEOLOGICAL SITES PRONE TO FLOODING

Of course, archeologists have not studied, surveyed, or investigated every flood-prone area in Maryland to determine the location of archeological sites. Following the mapping analysis described in Section 3, planners and archeologists may wish to conduct additional research about known sites, to better assess integrity and vulnerability (refer to Section 6), and/or to identify potential archeological sites within the areas affected by flooding.

A research design should guide where to invest the time, money, and labor to systematically investigate an area. An outline of what to include in a research design is provided in MHT’s Standards and Guidelines for Archeological Investigations in Maryland specific to the stage of archeological research being undertaken (survey, evaluation through test unit excavation, etc.). In general, the research design sets the parameters and focus of the investigation, provides the theoretical framework for answering questions about the past, and outlines the methods through which the investigation will be conducted. Depending on the project goals and the capacity available, research might proceed in several different ways, including predictive modeling, survey, and field testing, outlined below.

A number of factors may also constrain research and therefore affect the research design, including available time and resources, property access, and consultation with the public. In Maryland, permits are required to perform archeological investigations on state-owned lands, state-controlled lands, in caves, and on certain private properties. This includes state-owned or state-controlled submerged lands. Researchers need landowners’ permission to enter private property and conduct investigations, and property owners may also share personal knowledge about archeological resources on the property, as well as changes they have observed in the micro-environment during their tenure on the land. For these reasons, establishing and maintaining good relationships with landowners is strongly recommended.

**Predictive Models to Identify Archeological Sensitivity**

Predictive modeling is one method to determine the potential archeological sensitivity of an area (i.e., its likelihood to contain archeological resources). Predictive models are developed by analyzing human patterns of interaction with landscapes, using a combination of environmental, cultural, and historical data to determine potential locations for prehistoric activities and settlement. Predictive models should be projectspecific, but will often share many variables in common, such as distance to water or the nearest transportation route, slope, soil type, soil drainage, etc. Archeologists typically conduct the analysis and develop the model in GIS. Although primarily used to identify where to conduct field survey, predictive modeling can also be used to test theories on human settlement based on characteristics observed at the locations of similar sites (refer to Case Study #3 in Appendix 1).

Predictive models will usually identify areas of high, moderate, and low potential for the presence of archeological resources, based on parameters and questions set forth in the research design. For the purposes of this guidance document, a predictive model would map the potential location of archeologically sensitive areas in relation to flood hazards. The data can then be used to guide planning for flood mitigation and make decisions about where and how to conduct field survey (refer to Section 7). It should be
noted that a predictive model is only as good as the data and variables that go into it. The biases and prior knowledge of the model designer contribute to the utility of the model. (For additional information, refer to “Predictive Modeling” in Appendix 3 as well as Case Study #3 in Appendix 1.)

Archeological Survey and Documentation

Depending on the project goals and research design, archeological survey and documentation may be necessary to locate unidentified sites and/or to gather additional information about known sites. It can also be used to ground-truth predictive modeling. Any archeological project using state or federal funding will be required to conduct survey and documentation in compliance with state and federal standards, as described below. Projects undertaken entirely by local governments or private entities are strongly encouraged to comply with these standards and to share research findings with MHT, to ensure that data remains complete and accessible for the future.

Secretary of the Interior’s Standards for Archeological Documentation. The Secretary of the Interior’s Standards for Archeological Documentation provide a framework for the systematic and consistent collection of data when identifying and evaluating archeological sites. The philosophy of the Standards is to take the lightest touch possible, requiring that researchers first examine existing information and only supplementing with new investigations as needed. Excavation methods are destructive even when they are done in accordance with the Standards; therefore, limiting site disturbance (sub-surface testing or excavation) is always a goal when investigating archeological resources.

Standards and Guidelines for Archeological Investigations in Maryland. Developed by professional archeologists on MHT’s staff, the Standards and Guidelines for Archeological Investigations in Maryland provide consistency for recording archeological sites in Maryland and completing MASS forms, along with the accompanying report in accordance with the Secretary of the Interior’s Standards for Archeological Documentation. While primarily geared towards compliance archeology for state and federal project review, MHT’s Standards and Guidelines is flexible enough to be applied to other archeological investigations, such as work completed to meet local requirements, research projects, and public archeology projects.

MHT prefers approaches that focus on using pedestrian survey and remote sensing first, with physical excavation as a secondary method for gathering data. However, subsurface testing and/or excavation may be necessary, due to field conditions or other factors outlined in the research design. The level of effort should be commensurate with the requirement to evaluate the archeological resources for future investigation, determine their significance, and recommend adaptive strategies for the management of impacts to the resources.

Pedestrian Survey. Ideally, archeologists will utilize both terrestrial and marine pedestrian survey during the investigation of archeological resources in areas endangered by coastal hazards. In addition to the information collected relating to archeological resources, surveys provide an opportunity to record observations of existing conditions and refine the vulnerability analysis (refer to Flood Impacts in Section 3 and Section 6). A better understanding of an area’s vulnerability can inform adaptive strategies for the treatment of a site and help establish a baseline of existing
conditions for use when tracking and recording future damages to a site or area.

If approaching “pedestrian” survey by water, researchers should note that state waters include tidal waters up to the mean high tide line and three miles from the coastline, as well as non-tidal waters that were navigable under the laws of the United States as of April 28, 1788, up to the ordinary high-water mark. A permit is not required to inspect, study, explore, photograph, measure, record, conduct a reconnaissance survey, or otherwise study a submerged archeological historic property in Maryland, if the use or activity does not involve excavation, destruction, or substantive injury to the historic property or its immediate environment. For more information on terrestrial and underwater archeology permits, visit MHT’s website under Permits for Archeology on State Property.

**Remote Sensing.** Remote sensing is a surface or sub-surface investigative technique that allows for the collection of data through no or limited physical contact with the subject or object under study. Whereas physical excavation is destructive, ending in the removal of at least some portion of the site, remote sensing techniques do not harm a site. This approach requires specialized equipment and training for use and to interpret data. (To learn how archeologists used remote sensing at Calverton, refer to Case Study #4 in Appendix 1.)

Remote sensing techniques can be limited if obstacles, such as heavy vegetation or forest, exist between survey equipment and the target area for survey. However, remote sensing is faster than excavating shovel test pits across a landscape and can identify areas with a high potential for archeological resources. Archeologists analyze data from remote sensing survey to guide where and how additional investigation should occur.

Magnetic susceptibility, magnetometry or gradiometry, electrical resistivity, and ground penetrating radar are all geophysical remote sensing techniques that each have their specific strengths and weaknesses. An analysis of the utility of each technique is beyond the scope of this paper, but planners should consult with an archeological consultant with extensive experience in remote sensing before undertaking such a project. A knowledgeable consultant can advise on the best methods and equipment for a given environment or site type.

**Sub-surface Testing.** Sub-surface testing can be undertaken as part of survey (as in the case of shovel test pit excavation, described previously), evaluation of a site using formal test units, or salvage/mitigation of a site threatened by development or natural forces. Sub-surface testing entails artifact recovery as well as the documen-
tation of artifact locations and the recordation of any features encountered. If an investigation progresses beyond survey work, sub-surface testing usually involves the controlled excavation of formal test units under the supervision of a professional archeologist, who serves as the Principal Investigator (PI) for the project. The PI is responsible for completing the work, including fulfilling the research design, publishing the report, and ensuring the curation of artifacts and data. Thorough documentation of the site at this stage will usually involve survey and mapping equipment, photography, screening and sampling of soils, analyses, cataloging, and interpretation. The PI – who should meet the Secretary of the Interior’s Professional Qualification Standards – is there to ensure that each of these tasks meets professional standards of practice, including those outlined in MHT’s Standards and Guidelines.

**Reporting and Cataloguing Artifacts.** All phases of archeological investigation should end in a written report. The reporting requirements for compliance-related work can be found in MHT’s Standards and Guidelines for Archeological Investigations in Maryland, which includes the specific information required by the Secretary of the Interior’s Guidelines for Archeological Documentation. For academic archeological investigations, MHT strongly encourages adherence to the relevant portions of the Standards and Guidelines to ensure consistency in the recording and reporting of archeological properties. MHT incorporates data from archeological report submissions into the Maryland Inventory of Historic Properties archeological site files through either new or updated MASS forms.

Artifacts from archeological investigations in Maryland should be conserved and curated for future study in a facility with experience in the handling of both archeological data and artifacts. Such a facility should provide climate-controlled storage of the artifacts, as well as curation of the collection in bags and boxes that are conducive to the long-term preservation of the artifacts. Curators with experience in artifact conservation and cataloging will help steward collections and protect their long-term viability for research. In 2018, a technical update to MHT’s Standards and Guidelines provided curation and conservation standards for collections undergoing permanent curation at the MAC Lab. These guidelines can be used as a benchmark for evaluating curation practices and facilities.
5. EVALUATING AND DESIGNATING ARCHEOLOGICAL SITES

Of the 14,153 archeological sites that have been identified in Maryland (as of June 2019), only 2,435 (17%) have been evaluated to determine their eligibility for the National Register of Historic Places, the official list of the Nation’s historic places deemed by the National Park Service to be worthy of preservation. Authorized by the National Historic Preservation Act of 1966, the National Register of Historic Places and its criteria (described below) underpin federal and state historic preservation programs. If an archeological site is recognized by MHT or the National Park Service as meeting the criteria for National Register eligibility, then that site is understood as “historic” by federal and state agencies. In the case of federal or state undertakings (permitting, funding, construction, etc.), this means that the federal or state agency must consider ways to avoid, minimize or compensate for harm to the historic property (refer to Section 2). Archeological sites in Maryland that are listed in, or determined eligible for listing in, the National Register of Historic Places are included in Medusa, with their relevant documentation (refer to Section 3).

Of the 2,435 sites evaluated, 318, or 13%, were determined to be eligible for listing in the National Register, while 2,117 have been determined to be ineligible for the National Register. This disparity underscores the importance of professional evaluation: just because a site exists, it is not necessarily significant. While it is possible to determine an archeological site important for protection or research due to local cultural associations, National Register eligibility is, by far, the most common standard by which archeological sites are prioritized for treatment. National Register eligibility is evaluated by examining a site’s integrity and significance.

**Integrity.** Integrity relates to the ability of a site to demonstrate its significance and to retain most, if not all, of the aspects that make it significant. The integrity of the site will help determine whether it is a viable candidate for further research, though archeologists use a variety of factors to make that decision. One of the most important factors in determining the integrity of the site is whether provenience within the site remains intact. Provenience is the three-dimensional location of an artifact, ecofact, or feature that allows archeologists to determine its relationship to other artifacts, ecofacts, or features on site. Archeologists record both the horizontal and vertical location of an archeological find to evaluate its context within the site. This provenience is, in many ways, more important than the artifacts recovered from a site (refer to Section 2).

**Significance.** Once archeologists have determined that a site has integrity, the next step is to determine whether the site is significant. Archeologists may consider a site significant if it is a rare, unique, or unspoiled example from a specific time period, geographic region, or event. Sites vary dramatically in size and can have local, state, national, or international significance. It is important to stress, however, that the majority of recorded sites have not been evaluated for significance, due in part to the research designs and the purposes of the excavations.

To be determined eligible for listing in the National Register of Historic Places, archeological sites must meet one or more of the following criteria:

A. *association with events that have made a significant contribution to the broad patterns of our history;*
B. association with the lives of persons significant in our past;

C. embody the distinctive characteristics of a type, period, or method of construction, or that represent the work of a master, or that possess high artistic value, or that represent a significant and distinguishable entity whose components may lack individual distinction; or

D. that have yielded, or may be likely to yield, information important in prehistory or history.

Criterion D is most often applied to archeological sites. For a site to be eligible under Criterion D, sufficient research and testing must have been completed to demonstrate that a site not only has the potential to yield information, but that the information is important enough to make a significant contribution to the knowledge and understanding of defined aspects of prehistory or history. Typically, that evaluation is performed through sub-surface site testing (usually involving the excavation of formal test units) conducted in accordance with MHT’s Standards and Guidelines. An archeologist may recommend a site with both significance and integrity for a determination of eligibility for the National Register. Depending on the circumstance, this determination may be made by the involved federal or state agency in consultation with MHT or by the National Park Service. Listing in the National Register of Historic Places requires a public process and evaluation by the National Park Service.

Evaluation is an important tool for prioritizing valuable, or potentially valuable, archeological resources while those resources are still intact enough to provide additional information. It is also a necessary step in determining the appropriate treatment of the resources. Treatments can include, but are not limited to, additional research, interpretation, stabilization, and field survey. In evaluating resources vulnerable to flood hazards, treatment options should also include potential adaptive strategies for flood protection. At this time, flooding and inundation threatens archeological sites from all time periods in locations across Maryland. Most have never been evaluated. The artifacts and data recovered from these sites will be all that remains once the sites are destroyed or become inaccessible.
ARE CEMETERIES ARCHEOLOGICAL SITES?

Although largely underground and amenable to exploration using archeological techniques, burial sites represent a unique type of historic resource. Their value often centers around aesthetic beauty or their significance to living descendants or affiliated groups. Unlike archeological sites, cemeteries do not have a high potential to yield information about the lives of historical persons, social and economic trends, architecture and design, or other characteristics more typical of places where people have lived and left traces in the environment. Because of this, as a property type, cemeteries are not normally considered eligible for National Register listing (NPS 1992). Although biological information about buried humans can be gleaned from cemetery sites, MHT generally discourages the excavation of burial sites solely for the recovery of biological data as archeological research.

MHT does not maintain a dedicated inventory of burial sites. If cemeteries appear in MHT’s records, those with visible above ground features (grave markers, monuments, boundary markers, furniture, ornamental plantings, etc.) are generally inventoried as architectural or landscape resources, in the MIHP. Those lacking such features are often inventoried as archeological resources, via MASS forms. Many burial sites are inventoried as part of architectural complexes, such as a family cemetery located on a nineteenth century farmstead, and some burial sites may be listed in both the architectural and archeological inventories. Occasionally a burial site may possess architectural or landscape design or artistic qualities that distinguish it, or it may be the only surviving site associated with an important historical figure. These considerations may render a burial site eligible for National Register listing. In these cases, researchers may find information about inventoried cemeteries in Medusa, but it is important to note that MHT’s data is incomplete and largely incidental, and researchers are encouraged to seek additional information elsewhere.

Many counties maintain inventories at the local level. As of July 2019, ten counties have ordinances that protect or prescribe the treatment of burial sites. MHT encourages local planning for cemeteries and can provide technical assistance for communities that wish to take these resources into consideration. As with other types of historic properties, treatment depends on the circumstances of the property, the needs and resources of property owners, and the will of the community. When cemeteries are threatened by natural processes, some communities choose to intervene, and others prefer to allow the burial sites to return to the earth. Further information on cemetery law, the state of cemetery data maintained by counties, and technical assistance can be found on the MHT website.
With limited resources to conduct investigations, planners and researchers must prioritize new survey and documentation efforts. Factors for prioritization might include, but are not limited to:

- Significance, or potential significance, of the archeological site or potential resource;
- Underrepresented site types, cultural groups, or periods of time;
- Areas with high potential for unidentified sites, located in high hazard areas; and
- Areas that are less impacted by natural hazards.

There is no “right way” to prioritize; however, prioritization should be based on the flood vulnerability of known archeological sites (refer to Section 3), the results from archival and background research (refer to Section 3), and any predictive modeling (refer to Section 4). A “gap analysis” – an assessment of what data is missing within the archeological record – can guide investigations to potentially significant sites, unstudied or understudied site types, temporal periods, or geographic areas. MHT’s database resources, such as Medusa or the Archeological Synthesis Project, can be accessed and used by qualified archeologists to facilitate such gap analyses. However, because “underrepresented” may equate to being understudied, additional research phases may be needed to inform a gap analyses or develop archeological contexts.

Prioritizing significance may make funding more readily available for the work, as it is easier to justify expenditures for the most important (or potentially important) sites. However, there are disadvantages to using significance as the primary factor for prioritizing where to investigate and what to protect. Not all recorded sites have been evaluated (refer to Section 5), and potential sites are difficult to prioritize. Further, “significance” is a loaded term: what a researcher finds significant may not be understood or valued as significant by the community. Significance may seem like an expedient way to prioritize investigation and protection of sites, but it is more complex and may require more research than is apparent.

Prioritizing based on vulnerability focuses the investigation on locations with high potential for archeological resources that are also at high risk to flood hazards. For this method, it is necessary to conduct a more detailed analysis to comprehensively quantify the threat. Key questions include: How susceptible to erosion is a shoreline? What is the rate of shoreline retreat per year? What is the ability of saturated soils to quickly drain? How much rain can the soil absorb before liquefying and collapsing? What is the rate at which saltwater marshes are overtaking freshwater marshes and dry land? What is the extent of the predicted storm surge for the different hurricane storm categories? What is the extent of predicted sea level rise? Will these potential effects negatively impact archeological resources, and if yes, then how? This more in-depth analysis of hazards and their specific effects on archeological resources requires coordination between an emergency manager or floodplain administrator, a GIS analyst and a professional archeologist. (Refer to “Flood impacts to Archeological Sites” in Section 3 and Appendix 1: Case Studies.)

A detailed hazard analysis, conducted by the archeologist with a floodplain specialist, will also be useful when determining what, if any, actions can be taken to slow, reduce, or halt the detrimental effects of the flood hazards on locations (potentially) containing archeological resources (refer to Section 7). This analysis will also help forecast how long it might take for a vulnerable site to
be destroyed and lost for research purposes. For example, if a shoreline erodes at a rate of 20 feet within five years, and most sites lie at the water’s edge, waiting two to three years to begin an investigation will mean a potential loss of 8 to 12 feet of land, including archeological resources, before the project can begin. In some cases, the hazard may be so great that it makes more sense to prioritize research on areas less prone to flooding impacts (or at least immediate flooding impacts), than those archeological resources which cannot be salvaged by the time excavation funding and resources can be brought to bear. Finally, areas actively threatened by flooding are more likely to be targeted for mitigation by local or state government, especially if flood mitigation measures will protect life and property. This could be good or bad for archeological sites – good because mitigation may also protect sites further inland, and bad because the construction related to mitigation might damage or destroy any sites on the coast. If flood mitigation action requires state or federal permits or funding, it will trigger compliance with the National Historic Preservation Act and the Maryland Historical Trust Act (refer to Section 2).

Of course, all prioritization decisions involve some acceptance of loss in areas that were not prioritized for investigation or protection. Prioritization privileges the selected sites over other sites that might also be endangered by natural hazards. Because of this, as much as possible, decisions regarding prioritization should be made with community input and only after careful consideration of background research and an analysis of the flood threat and area’s vulnerability (refer to Section 3).
7. IDENTIFYING, EVALUATING, AND PRIORITIZING MITIGATION OPTIONS

Through a hazard mitigation planning process or preservation planning process, a local government may wish to address potential harm to archeological sites based on established priorities (refer to Section 6) or as part of a larger community flood mitigation project. Flood mitigation strategies for archeological sites fall into four broad categories: site stewardship, additional evaluation/investigation, protective measures (can be either built protections or planning activities), and no action, each of which are discussed in detail below.

**Site Stewardship**

Local municipalities concerned about the loss of archeological resources to flooding and climate change should consider developing a site stewardship program. Site stewardship involves tracking and recording the existing conditions at a site, possibly including the collection of diagnostic artifacts revealed due to flooding at the location. A site stewardship program need not be complicated. At a minimum, the program requires a field visit form, a photograph log, and a volunteer application. A local planner or dedicated volunteer can help organize site documentation visits if they know, or have been made aware, that a resource is under threat. By simply maintaining a list of volunteers with an interest in archeology (such as local ASM chapters, Boy Scout Troops, fraternal organizations or philanthropic groups), and creating a basic conditions assessment or site documentation form (field visit form), a local planner can provide the basic tools needed for such a program. If such activities take place on private land, a property owner will need to grant access, and a planner can serve as an intermediary to coordinate with the landowner. Artifacts, if they are collected, will have the same conservation and curatorial needs as described in previous sections.

A lot of information can be salvaged by simply collecting displaced artifacts (if the program supports collection), documenting the conditions of their displacement (i.e., the hazard), recording the artifact's location and type, and reporting this information back to the local government or whomever administers the site stewardship program. While out of their original context, such artifacts can provide clues as to what resource types are nearby and potentially in less-threatened areas. Such data can then be used to make informed decisions about future treatment, documentation, or salvage. A well-constructed field visit form should capture sufficient data to help in the prioritization process. A field visit form should capture standard information, including date and name of volunteer, the location, site name and number (if known), site conditions, site vulnerability, and visible features and artifacts. In some cases, information may warrant consultation with MHT and an update of the state’s site data. Field collection captures a “snapshot” of the site in

In 2014, the MHT Board of Trustees presented a Maryland Preservation Award honoring the Crum Family of Frederick County, the Archeological Society of Maryland, and Towson University for their stewardship of the Biggs Ford prehistoric village.
time, making it possible to begin tracking change over time at a given resource.

Site stewardship programs may serve as a tool for public outreach about the effects of natural hazards, including climate change, and for educating the public on the proper and ethical treatment of archeological resources. These programs can be established as public-private partnerships between local government and academic institutions, nonprofit groups, and landowners. Program guidelines should address the program’s purpose, requirements for participants, whether the program supports artifact collecting (including why or why not), and a code of ethics.

Stewardship programs typically rely heavily on volunteer labor. Volunteers may be professional archeologists, people with an interest but no experience in archeology, and everyone in between. Training and education are the hallmarks of a good stewardship program, and topics might include: ethics, “Archeology 101,” artifact identification (if the program supports collecting), the prehistory and history of the area, field safety, how to assess site vulnerability, and how to record existing conditions.

These partnerships require trust: that the volunteers will abide by the code of ethics and that the local government or program sponsor will provide volunteers with the training they need. With care and investment, site stewardship programs can play an important role in developing and prioritizing mitigation strategies for vulnerable sites. (Refer to “Site Stewardship” in Appendix 3 for more information on stewardship programs.)

Additional Evaluation and Investigation

In some cases, following archival and background research, predictive modeling, and/or field survey, the archeologist might determine the need for additional investigations to gather sufficient data (refer to Section 4) to evaluate the archeological resources and/or make a formal determination of significance (refer to Section 5). Under these circumstances it might be prudent to include objectives in the research design that relate to archeological resources and flood hazards. For example, in addition to the objectives listed in the Standards and Guidelines for Archeological Investigations in Maryland, consider including objectives that address the effects of flood hazards:

- Quantify the threat to the site by flood hazard,
- Determine the horizontal and vertical extent of the damage to the resources by those hazards, and
- Analyze adaptive methods to determine additional management strategies for the project area.

Protect in Place

Successfully protecting archeological resources reduces or (more rarely) eliminates the effects of the hazard. Hazard mitigation projects, especially those funded by FEMA as part of a hazard mitigation plan, are used to protect the life and safety of people, infrastructure, buildings, and sometimes agricultural land. (See MHT’s Flood Mitigation Guide: Maryland’s Historic Buildings, Chapter 2 for more information about the hazard mitigation planning process.) These projects do not usually prioritize undeveloped land or culturally significant areas, such as archeological sites, for protection, in part due to the federal require-
ment (referenced in FEMA’s Hazard Mitigation Assistance Guidance) that the financial benefit of the project must outweigh the cost of construction and maintenance.

For these reasons, hazard mitigation projects that protect archeological resources are likely to be part of a larger mitigation effort, typically funded through federal or state sources. Through federal and state project review, protective measures for archeological sites can be included in the overall project design. Any flood mitigation measures should consider not only the effect on the area prioritized for protection, but also how the treatment might affect adjacent areas and submerged archeological resources. Some mitigation measures may adversely impact archeological sites if soil removal and filling are required in construction.

For natural-based protections like ecological restoration (dune or marsh reconstruction), or habitat restoration (creation of an oyster reef that is a natural breakwater), project justification may be based on the environmental benefits of the projects, rather than the benefit of protecting cultural resources. Archeological resources located in urban settings can also be protected by natural-based protections. However, much of the focus of flood protection in urban settings involves stormwater management (including changes to infrastructure) and hard barriers such as floodwalls, all of which can negatively impact archeological sites, as described below.

MHT’s Flood Mitigation Guide: Maryland’s Historic Buildings (Section 3, Mitigation Options) provides a detailed overview of different community-wide and property-specific protective measures, including brief analyses of their impacts on cultural resources. Rather than replicate that guidance, this document outlines a few of the most common flood mitigation options for archeological resources, and it may be used in tandem with the Flood Mitigation Guide. In some cases, planners may choose to prioritize the protection of some archeological sites in a way that sacrifices others. For example, protecting inland sites may mean damaging or destroying coastal resources through the construction of hard shoreline projects such as seawalls, bulkheads, and armoring projects. In cases that may require trade-offs, planners and archeologists should carefully analyze local archeological data and prioritize in consultation with the public and, ideally, MHT.

**Flood Barriers.** Seawalls, levees, dikes, and embankments are all examples of large-scale flood barrier projects. When located along a river or coastline, these walls keep the water in the river channel or tidal body and prevent water from spilling into towns and agricultural fields, where it could endanger lives, damage buildings and infrastructure, and drown crops. These barriers...
are coupled with pump stations located at critical points to pump water that overtops the wall back into the river or tidal body.

Construction of large-scale flood protection always involves ground disturbance and is likely to damage/destroy any subsurface archeological resources. Barriers are typically constructed to meet a specific kind of storm risk. If a storm of a greater magnitude occurs, the water will overtop the barrier, and even if there are pumps, it could still flood the “protected” areas behind the wall. These types of protection can also cause negative environmental impacts if they sever the natural connection between the water and the land, destroying habitat and interfering with the natural functions of the floodplain.

Typically, barrier projects are funded by federal entities like the U.S. Army Corps of Engineers or FEMA (and administered through the Maryland Emergency Management Agency) and will trigger compliance with Section 106 of the National Historic Preservation Act and the Maryland Historical Trust Act (refer to Section 2).

Stormwater Management Systems. A stormwater management system can include drainage ditches, culverts, subsurface piping, water storage areas, retention ponds, and pump stations. These systems can be overwhelmed due to increasingly intense storms, undersized or older systems that are not designed to handle the current precipitation patterns, and the lack of routine maintenance. Generally, the engineered subsurface systems protect more urban areas, while ditches and culverts provide drainage in rural areas.

The construction or expansion of stormwater management systems usually involves some type
of ground disturbance and is likely to damage or destroy subsurface archeological resources (although improved stormwater management may provide protection as well). On the other hand, if existing systems fail, the effects can be catastrophic: archeological resources could be inundated and saturated for days with contaminated floodwater. As with any large-scale project, federal or state funding or permits will likely be involved and trigger compliance with Section 106 of the National Historic Preservation Act or the Maryland Historical Trust Act.

**Natural Infrastructure Solutions.** Utilizing natural or “green” infrastructure, such as ecosystem restoration, can reduce the effects of storm surge by returning the floodplain to its natural water management function. Natural infrastructure is often a better option for flood protection than “hardscape” infrastructure or barriers, because it provides ancillary benefits related to habitat restoration and improvement in water quality. For example, a healthy dune system can absorb the impact of storm surge and high waves and prevent or delay flooding by providing a natural barrier against flood and wind-driven storm surge. Coastal wetlands can reduce the velocity, depth, and wave energy of the storm surge. The extent to which a wetland can reduce the effect of storm surge is dependent on the characteristics of the wetland such as the geography, size, and type of wetland. Wetlands also function as natural sponges, storing excess flood water. Natural breakwaters, like oyster reefs, help with wave attenuation, reducing the impact of the surge. Natural infrastructure is often preferred for protecting preserves and parkland, or when using natural areas as buffers for developed areas, like the dune system protecting Ocean City, Maryland.

In many cases, natural infrastructure restoration can serve a dual purpose by also protecting archeological resources located in those areas, with less of an impact than barrier or hard infrastructure development. As a result, these adaptive measures can be more suitable to protecting archeological resources in undeveloped or rural areas. Natural infrastructure projects, whether or not they require compliance with the National Historic Preservation Act or the Maryland Historical Trust Act, still involve changes to the environment and should take care to ensure the protection of archeological sites in the design and implementation phases.

Natural infrastructure projects have different funding streams than structural projects and have different requirements related to environmental benefits. These projects may be undertaken by forming partnerships with environmental nonprofits, either through collaborative fundraising or volunteer efforts. For example, the Chesapeake Bay Foundation conducts oyster reef restoration projects, creating living breakwaters composed of oysters, which are natural filters and improve water quality. A joint project with the Foundation could both protect archeological resources and improve environmental conditions in the Bay.

**Shoreline Protection.** Both “hard” structural solutions and natural infrastructure solutions are used to address shoreline loss due to wave action and coastal erosion. Examples of hard structural solutions include revetments and riprap (fortified slopes or banks constructed from large stones or pieces of concrete); groins (oriented perpendicular to the shoreline; constructed from large stones or pieces of concrete); jetties (oriented parallel to shoreline, constructed from large stones or pieces of concrete constructed

---

7. IDENTIFYING, EVALUATING, AND PRIORITIZING MITIGATION OPTIONS
on either side of a coast inlet); and breakwaters (can be constructed from large pieces of stone arranged in a linear or curvilinear form with one end connected to the shoreline).

While hard structural solutions are most often used to protect shorelines, they have the adverse effect of causing erosion in adjacent, unprotected stretches of coastline, and these structures disrupt the relationship between land and water and subvert the natural functions of the floodplain. Selection of which protective measure to employ should be based on the geology, geography, and the hydrology of the site and consideration of how it could affect adjacent properties.

Soft or natural shoreline protection (sometimes called “living shorelines”) include dune systems, natural breakwaters like shellfish reefs, wetlands, and/or slope stabilization through plantings and ground cover management. Unlike natural shorelines, reconstructed dunes and wetlands are engineered solutions that require periodic maintenance, such as replanting or repeated placement of fill materials that trap sediment for plantings (sand, fiber mats, fiber logs or shell bags), to ensure that they take root and thrive on their own. Revegetating slopes and encouraging soil retention may also help stabilize denuded, failing shorelines. Although less costly to implement, this type of protection can be difficult to achieve, especially in cases where the slope erodes faster than vegetation can be established and/or where the slope ratio is closer to vertical than horizontal. Often, slope stabilization is used in conjunction with natural infrastructure, where a living shoreline is established at the toe of the slope to reduce wave energy, protecting the slope from impact and allowing time for the establishment of groundcover on the slope.

**Waterway Use Planning.** Waterway use planning, overseen by the Fishing and Boating Service at the Maryland Department of Natural Resources (DNR), seeks to improve life safety for boaters and address a variety of environmental issues like coastal erosion and water quality, typically by regulating recreational and commercial use of watercraft along a particular waterway. Where archeological resources are succumbing to the effects of shoreline erosion due to heavy traffic by boaters, DNR can assist property owners in developing a shoreline management plan that includes archeological site protection while addressing the causes of the accelerated erosion. Strategies might include reducing boat traffic, establishing low or no wake zones, and limiting the types and sizes of boats on the waterway. A shoreline management plan may be developed in conjunction with a watershed management plan and/or with natural infrastructure shoreline protection projects to further environmental goals for pollution reduction and wildlife habitat reconstruction.

**Mitigation Banking.** Mitigation banking does not refer to flood mitigation, but rather the restora-
tion of a wetland, stream, or other aquatic resource as compensation for unavoidable adverse impacts to aquatic resources under federal, state, or local wetland regulation. It is similar in concept to mitigation for harm to historic and cultural properties, established through consultation under Section 106 of the National Historic Preservation Act. Mitigation banking for aquatic resources is typically more stringent than mitigation for historic and cultural properties, requiring a project’s ecological success and long-term protection. If archeological sites or areas of high archeological sensitivity occur in areas suitable for mitigation banking, selection of bank areas could be done with both goals in mind. (More on mitigation banking can be found in Appendix 3.)

No Action

MHT’s Standards and Guidelines for Archeological Investigations in Maryland refers to the acceptance of loss as a rare occurrence. Sadly, current flood hazards, coupled with those projected to increase with climate change, means that unavoidable loss may become more common. In areas of extreme coastal erosion, the shoreline loss may occur too quickly to meaningfully investigate areas under threat. Areas actively converting from dry land to marshland and freshwater marshes converting to saltwater marshes transition too quickly for vulnerable, fragile archeological resources to withstand those changes. Sites which are actively degrading may not have enough left to evaluate by the time the fieldwork begins or to conduct further investigation after the site has been surveyed. These sites are among those colloquially described as “goners”—the sites that will not survive another generation without extraordinary measures to save them (Berenfeld, 2015: 6).

In some cases, “no action” may become the best possible alternative, especially for sites that may already lack integrity or significance, making them less able to convey information that advances our understanding or knowledge of the past. For sites at risk, the decision to take no action should be based on a careful analysis of the background and archival research, additional survey (if appropriate), and a thorough understanding of the vulnerability of the archeological resources. Using all the information at hand to decide when to let sites go is a difficult decision, but there are too many resources at risk to investigate and save all of them.

Salvage Archaeology

Salvage or “rescue” archeology is sub-surface excavation, usually undertaken at speed, to document a site and collect archeological data when destruction is imminent. Although salvage archeology is not ideal, it may be the only viable option for data recovery under certain circumstances. Unfortunately, unless a local jurisdiction has an archeology program or a standing arrangement with an archeological consultant, it is unlikely that the necessary funding, expertise, and resources can be mustered to salvage an exceptional, but threatened, site.

As always, salvage archeology should only be undertaken by, or under the guidance of a qualified archeologist (refer to Section 2). Planners and archeologists should consider the following criteria in determining whether to conduct salvage archeology.

1. The site should be under imminent threat of destruction (within a few months to 1 or 2 years). Justification for this threat assessment should be based on predictive model-
ing, documentation of erosion rates from site stewardship activities or other monitoring, or an assessment by a professional archeological consultant.

2. The site appears to have intact cultural features which will be lost or are under active erosion.

3. A preliminary assessment of the site (at a minimum) has been made to determine the site type, the cultures or communities represented, and time periods in evidence. If a resource type is well-represented across Maryland, salvage archeology may be a wasted or redundant effort.

4. Sufficient resources, including a qualified PI, can be brought to bear to ensure that rigorous scientific excavation, documentation, and publication will be carried through to completion.

5. All required permissions and permits have been obtained.

6. Consideration has been made for the final disposition of the artifact collection and records (i.e. conservation and curation).

7. There are no other reasonable alternatives to salvage and the resource is simply too important or potentially.

Because excavation destroys an archeological site, salvage archeology should be avoided if other investigative alternatives are feasible.
8. CONCLUSION

Although floodwaters threaten many known and as-yet-unidentified archeological sites along Maryland’s coasts and waterways, planners and archeologists can work together to prioritize and manage areas at risk and protect our past for future generations. MHT looks forward to assisting communities around the state as they begin these efforts by helping to connect them to funding resources, technical assistance, and each other.

Six hundred years ago, this farm field along the Potomac was home to a large Native American village with several houses surrounded by a tall palisade.

APPENDIX 1: CASE STUDIES

The case studies provide specific examples of the different steps involved in the process of managing archeological site vulnerability to flood hazards. These case studies illustrate practical examples of success stories and should not be interpreted as the best or the only approach.

Case Study 1: Using GIS Applications to Determine Vulnerability to Shoreline Erosion

One method for approaching how to determine the vulnerability of archeological sites to shoreline erosion is to use a GIS application to calculate the rate of erosion. The Longwood Institute of Archeology conducted an Archeological Shoreline Survey of Portions of Lancaster, Mathews, Middlesex, and Northumberland Counties, Virginia in June 2017 (Rose et al). Their report provides an overview of the different GIS tools available for calculating shoreline change and a detailed method for determining rates of shoreline change. The Institute used the AMBUR (Analyzing Moving Boundaries Using R) software package to calculate the rate of shoreline change. The AMBUR program was developed to analyze historical shoreline change and changes in other boundaries. The software is compatible with ArcGIS and open-access GIS. In AMBUR, the Longwood team georeferenced three aerial imagery datasets (1937, 1994, and 2013) and selected weighted linear regression models to calculate the rate of shoreline change. The program created baselines and transects at a 5-meter interval. The results of the analysis pinpoint the rate of shoreline change at each five-meter interval. The rates of change were identified on a scale that ranged from very high accretion (greater than 10 ft/yr) to very low accretion (0 to 1 ft/yr) and very low erosion (-1 to -2 ft/yr) to very high erosion (greater than 10 ft/yr).

AMBUR produced an analysis table containing archeological site number, average weighted linear regression (ft/yr), site distance to water (ft), years to reach site, site depth (ft), projected life span of site (site depth divided by average weighted linear regression), and shoreline trend (landward or seaward). Based on the AMBUR analysis, the actual rate of shoreline accretion or retreat is identified at each archeological site along with an estimate of how long it will take for the shoreline to completely erode and destroy the site.

This is a complicated process and requires expertise in conducting GIS analyses, statistics, and archeology. The process also requires a substantial amount of time for the input of data and to run the AMBUR program. However, the results provided by the program allow for planning to address the impacts to a site based on a specific, defensible timeline (e.g. 5 years, 10 years, etc.). One of the advantages of the AMBUR program is its ability to analyze highly curved shorelines: something other baseline and transect shoreline models have difficulty determining. Another advantage is that the program’s method for forecasting shoreline changes can also be made using a variety of rate calculation methods in addition to weighted linear regression. These advantages make AMBUR a powerful tool for assessing vulnerability due to shoreline erosion.

Case Study 2: Determining Vulnerability to Multiple Hazards and Prioritizing Actions

This case study also highlights the use of GIS applications in determining vulnerability to various flood hazards. In their Archeological Survey of Threatened Cultural Resources on Hunting Creek, Applied Archeology and History Associates, Inc.
evaluated the vulnerability of archeological sites to shoreline erosion, storm surge, and sea level rise and prioritized sites for further action based on that information. Field survey was conducted from the water via canoe, with investigators beaching the craft below mean high tide, as to remain on state land and not enter private property. Field visits included a visual inspection of the shoreline, photographs, and using a handheld GPS device to record site locations. The sites were plotted on USGS maps and aerial photographs.

Investigators used the Maryland Department of Natural Resources’ MERLIN (Maryland Environmental Resources and Land Network) GIS application to determine the vulnerability to sea level rise, storm surge, and shoreline erosion. MERLIN allows users to customize existing base maps (e.g. historical shoreline erosion, sea level rise, etc.) and import their own data. The location information for each site was imported into MERLIN and compared to the historical shoreline maps. In comparing their observations of the shoreline to the maps, they found that the latest maps were mostly accurate except for a single area where the shoreline had receded more than 40 meters near one site. Vulnerability to shoreline erosion was calculated based on these attributes: maximum fetch, maximum water depth along

Case Study 2: Vulnerability and Cultural Ranking Table excerpted from: Archeological Survey of Threatened Cultural Resources on Hunting Creek, report produced for the Board of County Commissioners of Calvert County.
maximum fetch, compass orientation of maximum fetch, the presence/absence of shoreline breaks, and anticipated boat wakes. The attributes were analyzed in relation to the cumulative effect they could have on each site and then the site was ranked at low, medium, or high for erosion risk. More than half the sites in the project area were determined to be at high risk to coastal erosion.

MERLIN was also used to analyze site locations in relation to sea level rise and storm surge to determine the level of impact (high, medium, or low) for each hazard. Sea level rise maps are linked as a layer that can be added to the base map in MERLIN. However, for storm surge the National Weather Service’s SLOSH (Sea, Lake, and Overland Surge from Hurricanes) Model from 2014 needed to be imported into MERLIN. Vulnerability was ranked as high, medium, or low depending on the predicted impact of the hazard on each site.

After analyzing the vulnerability, sites were ranked by potential research value. The investigators acknowledge that the ranking is subjective, and disadvantages newly recorded/unstudied sites, while favoring known/studied sites. Nonetheless, sites were ranked using professional judgement, by the type and quantity of artifacts, site size and the dated components of the site. The research value rankings were compared to the vulnerability rankings for shoreline erosion, sea level rise, and storm surge. Because it is not financially feasible to investigate or protect all endangered sites, investigators prioritized sites that ranked high in potential research value that were at high risk to the three hazards. As a result, five out of 19 sites were recommended for further action.

This case study illustrates the use of an open source GIS application and free data from state and federal sources in conjunction with data obtained in the field to analyze vulnerability. It also illustrates a process of conducting fieldwork involving non-invasive survey (no subsurface testing) and using the observations and data collected in the field to truth and supplement the vulnerability analysis. This is one approach to determining vulnerability and using those determinations to prioritize which sites need to be targeted for further action.

**Case Study 3: A Predictive Model for Prehistoric Sites in the Lower Potomac**

A criticism of predictive modeling is that it is used as a tool to minimize fieldwork and not as a tool for examining spatial patterning of archeological sites (Verhagen and Whitley, 2012). However, examples like Strickland, Busby, and King’s work on identifying the Indigenous Cultural Landscape (ICL) for the Nanjemoy and Mattawoman creek watersheds creates a predictive model as a byproduct of identifying indigenous settlement patterns during the Late Woodland and Contact periods within the project area (2015). Their analysis for settlement patterning is based on how people moved throughout and utilized resources across the landscape. The process presented in their work could be adapted for use in identifying archeologically sensitive areas.

The ICL for the Nanjemoy and Mattawoman creek watershed was created to identify Native landscapes as they appeared during the Late Woodland and Contact periods along a section of the Captain John Smith Chesapeake National Historic Trail. The Trail travels along the waterways of the Chesapeake and follows Captain John Smith’s 1608 voyages in the Bay. The different ICLs iden-
tified along the trail are incorporated into the trail’s Comprehensive Management Plan and help guide decision making for conservation, education, historic preservation and economic development (Strickland et al., 2015). The methodology for developing the Nanjemoy and Mattawoman creek ICL included interviews with a broad range of stakeholders, extensive research, and GIS mapping and modeling.

Information was collected on hard copy maps from stakeholders who identified important locations within the project area such as locations of plants important to historical and contemporary indigenous people, water viewsheds, and water-based resources (Strickland, et al., 2015: 43). The informant information was entered into GIS as a data layer. Other data layers included the location of recorded Late Woodland and Contact period sites and a basic set of criteria for identifying ICLs that was developed by the National Park Service (NPS). NPS’s basic criteria is comprised of GIS layers for resources that would have been exploited by indigenous populations. The basic data set was supplemented by additional criteria that emerged during conversations with stakeholders, and which included locations that are threatened and in need of protection, as well as areas identified through historic ethnographic accounts.

Using GIS to analyze the layers of data, a predictive model was developed to identify landscapes “evocative of the ICL during Captain John Smith’s time” (Strickland, et. al., 2015: 62). The analysis also produced a settlement model for the two watersheds around the time of Smith’s journey. The location of prehistoric settlements is driven by the availability of exploitable resources, location of good agricultural soils in well drained land, and geologic formation. Settlement was also found to be dependent on the form and purpose of the occupation (settled villages vs. more temporary procurement sites). Based on the results of the statistical correlative studies, Strickland proposed a settlement model for predicting Late Woodland/Contact Period site locations in the Lower Potomac watershed for different settlement types (Strickland, et al., 2015: 41-42).

Case Study 3: Late Woodland/Contact period settlement patterns in the Lower Potomac watershed.
Source: Adapted from Strickland, Busby, and King, 2015
Taking this information and going one step further to pinpoint areas of archaeological sensitivity will require a closer look at Strickland’s data and modeling. However, the methodology for identifying settlement patterns could be replicated. This case study highlights a portion of the work done by Strickland, King, and Busby in identifying an ICL. Readers interested in following Strickland’s approach or in seeking to identify ICLs may find more information under “Predictive Modeling” in Appendix 3.

**Case Study 4: Significance as a Determining Factor for Prioritizing Investigation**

The Calverton Site provides an example of using significance to prioritize volunteer effort and limited research funding to target a threatened site for further investigation and evaluation. The work conducted at the site beginning in 2017 illustrates several concepts and investigative techniques described in this document. This case study is based on the work conducted at the site during the 2017 Tyler Bastian Field Session in Maryland Archeology, a joint effort by MHT and the Archeological Society of Maryland. The town of Calverton is depicted on a 1682 plat in the location of the site and previous investigations found evidence of 17th century colonial artifacts. Calverton was laid out in 1668 and was the second town in the colony of Maryland and the first town in Calvert County (Shearn, et al., 2017: 1). The Calverton site had been subject to past study including an NRHP nomination form that was prepared for the site in 1986, but not submitted to the NPS (Shearn, et al., 2017: 14). The site is threatened by an actively eroding coastline.

Calverton is an extremely rare and, thus, significant resource type: the remains of a 17th century town and county seat. The 1682 plat depicted the presence of a courthouse, jail, church, multiple dwellings, dependencies, and possibly a clerk’s office all laid out in linear fashion along the shore of Battle Creek. But the extent to which these resources had been damaged by erosion and storm events was unknown. Due to the potential significance of the site as an early planned town in the Maryland colony and the threat of losing more of the site to erosion, further investigation became a priority for County preservation personnel. The goals of the 2017 investigations were to identify what remains of the town and to determine the accuracy of the locations of structures indicated on the georeferenced 1682 map and the results of a magnetic susceptibility survey (Shearn, et al., 2017: 24).

Prior to beginning subsurface testing, the site was remotely tested using magnetic susceptibility. Magnetic susceptibility measures the “magnetizability” of surface soils, a variable that can be influenced by past human activity. The results produced a map of magnetic anomalies depicting areas of potentially high archeological sensitivity. These anomalies were overlaid with the georeferenced historical plat to identify areas in which to conduct subsurface investigations.

Subsurface testing consisted of shovel test pits in areas too dense to test using magnetic susceptibility and test units located in areas corresponding to magnetic susceptibility hot spots, three of which matched the locations of structures on the 1682 plat (Shearn, et al., 2017; 26). Surface collection was conducted along the beach below the coastline; artifacts were recovered from the excavation of a feature in the cliff profile in a location that may correspond to a house on the 1682 plat. ArcGIS was used to determine how much of the site has been lost to erosion by comparing the distribution of artifacts across the site to the...
orthomosaic map of the current coastline (an orthomosaic map is an aerial photograph that has been geometrically corrected to remove topographic relief, lens distortion, and camera tilt so that it has the same lack of distortion as a two-dimensional map), historical aerial imagery, the 1682 plat, USGS topographic maps, a 2015 shoreline study, and the bathymetric reconstruction of the shoreline (which shows the terrain of the creek floor as contour lines) (Shearn, et al., 2017: 75). The results indicated that approximately 30 meters of erosion has occurred, equating to a loss of roughly 3.7 acres. Despite this loss, the excavation demonstrated that substantial portions of the historic town remain and that the historic map appears to be relatively accurate (Shearn, et al., 2017: 85). Recommendations for adaptive strategies for Calverton included additional excavation of larger portions of the site, investigation of an adjacent property which has high potential for intact archeological resources related to Calverton, periodic site visits and collection of artifacts along the shoreline below the site; and tracking and recording the continued threat of erosion (Shearn, et al., 2017: 86).

Calverton is an example of a site that was previously identified as significant that was prioritized for further investigation because it is actively threatened with destruction through shoreline erosion. A research design was developed based on historical information, analysis, and informa-

Case Study 4: An interpretation of magnetic susceptibility data collected in May of 2017 based on comparison to the 1682 plat of Calverton. Source: MHT, 2017.
tion from past investigations. Both non-invasive and invasive methods of survey were used to recover information about the site. The information confirmed that the site is the town of Calverton, the historical mapping is mostly accurate, and that a good portion of the site remains intact. Based on an analysis of the results of the investigation, an updated NRHP nomination form was prepared that confirmed the site as potentially eligible for inclusion in the NRHP under Criterion D (an archeological site that has yielded, or may be likely to yield, information important in prehistory or history). Finally, recommendations were developed that address the need to gather additional data and to monitor the shoreline.

Case Study 5: Living Shorelines at Jefferson Patterson Park and Museum

The living shoreline project at Jefferson Patterson Park and Museum (JPPM) provides an example of the successful use of natural infrastructure to protect both archeological resources and agricultural land. JPPM is a 560-acre property located at the confluence of the Patuxent River and St. Leonard Creek. The property is home to many archeological sites representing 9,000 years of human occupation, a visitor center, the MAC Lab, and numerous other buildings. Shoreline erosion threatened the property, particularly along the river and at its confluence with the creek. Rather than utilizing hard structural protections to halt erosion, the decision was made to utilize soft (also called “natural” or “green”) methods of protection that included habitat restoration and allowing for normal coastal processes of sediment transportation to occur across the shoreline (refer to Section 7). The project involved constructing two different types of breakwaters, pocket beaches, and the placement of sills to prevent further erosion and encourage accretion along the shoreline. Breakwaters were placed in two locations: at the headland of the peninsula and along the shoreline of the Patuxent River where the shoreline was more vulnerable to erosion. The breakwaters at the headland were supported by sand fill placed behind them to create a beach.

Saltmeadow hay was then planted on the beach above the mean high tide to form a marsh to stabilize the beach, provide wave attenuation and additional protection from storm surge. An added benefit of the creation of the marsh was the development on an environment that now includes indigenous fish living in the shelter of the breakwaters, shorebirds who frequent the beach and marsh, and diamondback terrapins who nest there in the early summer months.

All the living shorelines at JPPM were tested by Hurricane Isabel in 2003. Although all protective measures suffered some negative impacts from the storm, they prevented losses to the shoreline.

Headland breakwaters and the pocket beach protect embankments from wave damage and erosion.
and succeeded in protecting the archeological resources. Funding for the project came from a variety of non-profit, state, and federal sources. This project demonstrates that a variety of natural solutions can be used to provide protection for archeological sites while also providing habitat for native species and restoring marshlands.

Case Study 6: Natural Shoreline Protection of a Prehistoric Ossuary
Another example of natural shoreline protection, this case study demonstrates that success is measured according to the goals of the protection project. Erosion along the banks of a waterway popular with recreational boaters had revealed the presence of human remains. MHT conducted a field visit to the site and determined that the remains were associated with a Native American ossuary (a location where human remains are re-interred once flesh has decayed). The ossuary was eroding out of a steep embankment due to the repeated impact of waves generated by boaters along the river.

MHT entered into consultation with the indigenous community on whose ancestral lands the ossuary is located to determine adaptive strategies for managing the impacts to the ossuary. All parties involved in the consultation were concerned with potential malfeasance should the remains stay uncovered. The indigenous community wished for the remains to continue their natural journey, thus the solution needed to ensure the protection of the remains while allowing for coastal processes to occur naturally. The agreed-upon action was to stabilize the riverbank, which would allow for a more controlled, but concealed, continuation of the movement of the shoreline. Fiber logs were staked at the toe of the slope to encourage soil retention to fill in behind the logs. Sandbags were laid against and stacked on top of the bank. Fiber cloth was staked to the top of the bank to hold soil in place. No planting was done at the time of the installation as work had to be done during winter to ensure the ossuary was protected immediately.

A recent visit to the site found that while the stabilization measures had not taken hold as was intended, it was nonetheless still serving its purpose. The vegetation at the top of the bank had grown in, forming a nearly impenetrable barrier. Approaching the shoreline from the river, displaced sandbags were immediately apparent, extending downstream to the point of the landform. The sandbag “wall” had slumped but remained in place covering the ossuary. The fiber logs were all gone, their location only identifiable by the line of wooden stakes that were still intact in the water. Some vegetation has opportunistically begun to grow in scattered locations on the articulated sandbags still against the bank. While

Even though the coir log is gone, and the sandbags are disarticulated, some sandbags remain in place protecting the embankment. Source: MHT, 2018.
this is not completely a success story in that the coir logs washed away and vegetation did not fill in to create a new, more protected natural shoreline, the protective measure still met the goals set forth at the outset of the project: to cover and protect the ossuary while allowing for nature to take its course. While some projects focus on stabilization for long-term protection, this project’s goal is to allow the ossuary to decay while safeguarding the human remains from disturbance.
APPENDIX 2: FUNDING SOURCES

Potential funding streams for investigation or protection of archeological resources at risk to flood hazards are presented below. There are also many grant programs that address the conservation of natural resources, and some of these might be used to protect or conserve archeologically sensitive areas. It is up to the researcher to think outside the box in utilizing natural resources grants to address the protection of archeological sites: the few programs discussed below are merely a starting point.

Federal
The U.S. Department of Agriculture’s Natural Resources Conservation Service has funding opportunities related to land conservation that could be used to protect archeologically sensitive land, provided it also serves environmental conservation needs and meets the criteria of eligibility. The U.S. Fish & Wildlife Service’s National Coastal Wetlands Conservation Grant Program could be used to protect, restore, and enhance coastal wetlands and their associated uplands. This could potentially be used to protect archeological sites in these areas or to restore and enhance wetlands that provide protection for upland areas where sites are located, depending on whether the project meets eligibility criteria.

State
The Maryland Department of Natural Resources’ Chesapeake and Coastal Grants Gateway provides technical and financial support for projects that improve the environment and increase resilience to climate change – the ability to withstand environmental changes – of vulnerable Chesapeake Bay communities. The grants fund studies, planning, and construction of projects that improve the recovery and restoration of natural resources, address flood risks due to climate change, and that use nature-based infrastructure to achieve those results. The grant program could be used for protecting sites or sensitive areas, but not for investigation.

The Maryland Emergency Management Agency manages FEMA’s Hazard Mitigation Assistance Grant Program. Under this program, FEMA has two grants dedicated to pre-disaster hazard mitigation (Pre-Disaster Mitigation Grant, PDM, and the Flood Mitigation Assistance Grant, FMA) and one post-disaster grant (Hazard Mitigation Grant Program, HMGP). These programs could be used for projects that protect vulnerable sites or archeologically sensitive areas in place, provided those protections also protect infrastructure or buildings. The intent of these projects is to protect buildings, infrastructure, people, and other assets. Cultural resources can be considered an asset. Investigation of endangered archeological sites might be possible under HMGP if that investigation also includes an analysis of the vulnerability of the sites to flood hazards and recommendations to eliminate or reduce their vulnerability. Project eligibility should be discussed with MEMA.

MHT has several grant programs that can support archeological investigation.

- The Certified Local Government (CLG) Program funds projects and education opportunities in Maryland’s 11 towns and 10 counties that have gone through the certification process. Archeological investigation is an eligible activity under the CLG grant guidelines.
- Archeological investigation is an eligible activity under MHT’s Historic Preservation Non-Capital Grant Program, which supports local governments and non-profit organizations that conduct research, survey, planning and educational activities involving cultural resources.

APPENDIX 4: REFERENCES CITED

Busby, Virginia R., Julia A. King, and Scott M. Strickland. 2015. Indigenous Cultural Landscapes Study for the Nanjemoy and Mattawoman Creek Watersheds. St. Mary’s College of Maryland, St. Mary’s City, Maryland. Prepared for the National Park Service Chesapeake Bay, Annapolis, Maryland.

Projects undertaken for resiliency planning and hazard mitigation may be subject to a range of federal and state environmental laws and regulations for consideration of impacts to cultural resources. The specific project circumstances, proposed activities, funding sources, and necessary permitting actions are all factors that will determine which requirements apply to a given project. For instance, when FEMA provides grant assistance to a local government to help fund hazard mitigation actions, FEMA considers project impacts on environmental and cultural resources, pursuant to NEPA and NHPA. If the proposed actions are located in federally regulated wetlands, the applicant may need to obtain a Section 404 permit from the U.S. Army Corps of Engineers for the proposed work. During planning for resiliency and hazard mitigation actions, it is important to identify all anticipated sources of federal and state involvement (including funds, permits and licenses), to facilitate successful integration of the various applicable federal, state, and local requirements. Depending on specific project activities, the following federal and state laws and regulations may be pertinent to a project sponsor’s consideration of cultural resources, although this list is not exhaustive:

The National Environmental Policy Act (NEPA) requires sponsors of projects receiving federal funds to consider natural and socioeconomic factors using a systematic and interdisciplinary approach before committing to a project. This process requires coordination with multiple environmental agencies to obtain information on cultural, socioeconomic and natural resources within the project area, documentation of any impacts upon those resources, and consideration of ways to avoid or minimize impacts as appropriate.

The National Historic Preservation Act (NHPA) – Section 106, along with its implementing regulations (36 CFR Part 800), requires projects receiving federal funds, licenses or permits (such as a Section 404 permit from the U.S. Army Corps of Engineers) to consider the effect of the undertaking on significant historic properties, including historic structures and archeological resources. Through consultation, federal agencies must identify and evaluate historic properties that may be affected by a project and develop measures to avoid, reduce or mitigate any adverse effects on those properties.

The Maryland Historical Trust Act of 1985 (State Finance and Procurement Article §§ 5A-325 and 5A-326 of the Annotated Code of Maryland) requires projects receiving state funds, licenses or permits to consult with the Maryland Historical Trust and consider potential impacts on significant historic properties, including historic structures and archeological resources. To ensure consistency for projects with both federal and state involvement, MHT follows the process set forth in 36 CFR Part 800 for reviewing state assisted actions.

Section 404 of the Clean Water Act prohibits discharge of dredged or fill material into wetlands and waterways unless proven that steps have been taken to avoid and minimize wetland impacts where practicable, and unavoidable impacts are mitigated through activities that restore or create wetlands.

Chesapeake Bay Critical Area Act establishes land use policies for development in the Critical Area which accommodate growth, minimize adverse impacts on water quality, and conserve the habitat of wildlife, and plants. The Critical Area is any area within 1,000 feet of tidal influence.
